Abstract— This paper proposes a fault-tolerant control technique against current sensors failure in direct torque controlled induction motors drives. Several important aspects are covered in the proposed algorithm, such as the detection of sensors failure, the isolation of faulty sensors, and the reconfiguration of the control system by a correct estimation. A logic circuit ensures fault detection by analyzing the residual signal between the measured and estimated quantities, while a single modified Luenberger observer performs the task of estimating the line currents, even when all the sensors are in the faulty state. In addition, a decision logic circuit isolates the erroneous signal and simultaneously selects the appropriate estimated current signal. The proposed scheme is tested on MATLAB/Simulink environment and experimentally validated in a laboratory prototype mainly containing a dS1104 card and 4 kW induction motor.

Keywords—fault tolerant control, fault detection, current estimation, induction motor, direct torque control, adaptive observer.

I. INTRODUCTION

Fault Tolerant Control (FTC) methods are crucial in variable speed drives used in critical and high-sensitivity applications, such as, space exploration, nuclear power plants, electric vehicles, air and rail transportation; in order to ensure system security, and uninterrupted operation, even with degraded performance, when an unexpected failure occurs in the variable speed drive. Consequently, a fault tolerant control strategy must be implemented to guarantee that faults are handled in such a way that there will be no damage.

Generally, variable speed Induction Motor (IM) drives need feedback information from a speed/position transducer, two or three current sensors and a dc-link voltage sensor at least [1], [2]. Unfortunately, sensors are very prone to failures, and for this reason several research results have been published regarding sensors fault-tolerant control, as well as Fault Detection, Isolation, and Reconfiguration (FDIR) methods [3]–[10].

The study in [3] presents a sensor FTC of an induction motor drive, based on the extended Kalman filter, and a reduced number of adaptive observers, to keep the operation of the system under the occurrence of sensors failures. In [4],

a fault-tolerant vector control is proposed. A logic circuit is used to identify the faulty current sensor. The missing current information is replaced by an appropriate stator current, which value is calculated from algebraic equations and from the other measured healthy currents. However, this approach is not practical in the event of a successive failure in the different sensors. A fault-tolerant control scheme is proposed in [5], in which an adaptive fuzzy logic-based observer is used to generate residuals, which analysis allows the detection, and isolation of the faulty sensor. However, the dynamic response of this scheme for isolating defective sensors is too slow. In [6], it is proposed a sensor fault detection and isolation scheme for an IM drive, based on currents estimation and rotor resistance variations, which are then used in a decision unit for the identification and isolation of the faulty sensor. In [7], a FTC technique against speed and current sensors failures in IM drives is proposed, and based on three adaptive observers with different inputs. However, this method is not suitable to achieve an efficient FTC in case of failures in two or three sensors. The results obtained in [8] offer a solution to the succession of faults in the different sensors but the number of the used adaptive observers is still three. Another type of FTC methods has been also presented in the literature, in which the sensors FTC algorithm changes the control according to the type of the faulty sensor, as proposed in [11]–[14]. A smooth FTC of IM drives with sensor failures is presented in [11], [12]. In the healthy state, the IM drive's operation is accomplished using direct torque control; indirect field oriented control is then used when the dc-link voltage sensor fails, and v/f control is utilized during current sensors failure. The major drawback of this method, as reported in [15], is that these techniques are experimentally difficult to implement.

This paper proposes a direct torque fault-tolerant control strategy for the current sensors failure in induction motor drives. Some features are distinct from the other proposed methods. First, the estimation of stator currents is performed using a single observer. Then, the method proposed here allows the detection of faulty sensors even when several sensors fail successively, case in which a decision unit, based on a logic circuit, performs the task of reconfiguring and isolating the effects corresponding to the faulty sensor. Finally, the proposed technique can be reorganized in an

adaptive way in the event of the loss of one or two sensors. The proposed scheme is simulated in MATLAB/Simulink environment, and experimentally implemented in a laboratory test bench under different operating conditions.

The remainder of the paper is organized into V sections. Section II analyses the direct torque control. Afterwards, section III describes the concept of the proposed FTC. Simulation and experimental results are presented and discussed in section IV. Finally, section V presents the main conclusion of the paper.

II. DIRECT TORQUE CONTROL OF THE INDUCTION MOTOR

The system equation below gives the induction motor model used in the present work.

$$\begin{cases} \frac{di_{s\alpha}}{dt} = -\left(\frac{R_s}{\sigma L_s} + \frac{R_r}{\sigma L_r}\right)i_{s\alpha} - \omega_r i_{s\beta} + \frac{R_s}{\sigma L_s L_r} \psi_{s\alpha} + \frac{\omega_r}{\sigma L_r} \psi_{s\beta} + \frac{1}{\sigma L_s} V_{s\alpha} \\ \frac{di_{s\beta}}{dt} = -\left(\frac{R_s}{\sigma L_s} + \frac{R_r}{\sigma L_r}\right)i_{s\beta} - \omega_r i_{s\alpha} + \frac{R_s}{\sigma L_s L_r} \psi_{s\beta} + \frac{\omega_r}{\sigma L_r} \psi_{s\alpha} + \frac{1}{\sigma L_s} V_{s\beta} \\ \frac{d\psi_{s\alpha}}{dt} = V_{s\alpha} - R_s i_{s\alpha} \\ \frac{d\psi_{s\beta}}{dt} = V_{s\beta} - R_s i_{s\beta} \end{cases} \quad (1)$$

where:

$V_{s\alpha}, V_{s\beta}$: (α, β) stator voltages,

$i_{s\alpha}, i_{s\beta}$: (α, β) stator currents,

$\psi_{s\alpha}, \psi_{s\beta}$: (α, β) stator fluxes,

R_s, R_r : stator and rotor resistances,

L_s, L_r : stator and rotor inductances,

ω_r : rotor angular speed.

$\sigma = 1 - \frac{M^2}{L_s L_r}$, given that M is the mutual inductance.

The electromagnetic torque is expressed by the following equation:

$$T_e = p(\psi_{s\alpha} i_{s\beta} - \psi_{s\beta} i_{s\alpha}) \quad (2)$$

The stator flux components are given in the system equation below:

$$\begin{cases} \psi_{s\alpha} = \int (V_{s\alpha} - R_s i_{s\alpha}) dt \\ \psi_{s\beta} = \int (V_{s\beta} - R_s i_{s\beta}) dt \end{cases} \quad (3)$$

The Direct Torque Control (DTC) basic idea is to estimate flux and torque instantaneous values only from the stator variables. The estimated torque is compared with the reference one given by the speed controller (PI controller in the present work), the resulting torque error signal is sent to an hysteresis controller (three-levels hysteresis controller is adopted in the present work) to get a control signal C_{Te} , which fed a switching look-up table. Likewise to the estimated flux, which is compared with fixed value of a stator flux magnitude, the resulting flux error signal is fed an hysteresis controller (two-levels hysteresis controller is adopted in the present work) to get a control signal C_{fLx} for the switchin look-up table. This latter uses flux and torque control signals in order to generate three control signals S_A, S_B and S_C for the three-phase inverter (see Fig. 4).

III. CONCEPT OF THE PROPOSED FAULT-TOLERANT CONTROL

In the proposed fault-tolerant direct torque control, two current sensors in phase-a, and phase-b are used in addition

to a dc-link voltage sensor, and an incremental encoder. Furthermore, using the control signals S_A, S_B and S_C , a voltage synthesizer construct the three-phase stator voltages applied to the machine from the voltage measured in the dc-link.

A. Stator Currents Estimation

In order to estimate the line currents, a modified adaptive observer is used, which gives high-performance estimation stator currents, based on the IM model, which is described by the following state equation:

$$\begin{cases} \dot{X} = A(\omega_r)X + BU \\ Y = CX \end{cases} \quad (4)$$

where:

$$X = [i_{s\alpha} \ i_{s\beta} \ \psi_{r\alpha} \ \psi_{r\beta}]^T; \quad Y = [i_{s\alpha} \ i_{s\beta}]^T;$$

$$U = [V_{s\alpha} \ V_{s\beta}]^T$$

and:

$$A = \begin{bmatrix} a_1 & 0 & a_2 & \omega_r a_3 \\ 0 & a_1 & -\omega_r a_3 & a_2 \\ a_4 & 0 & a_5 & -\omega_r \\ 0 & a_4 & \omega_r & a_5 \end{bmatrix}; \quad B = \begin{bmatrix} \frac{1}{\sigma L_s} & 0 \\ 0 & \frac{1}{\sigma L_s} \\ 0 & 0 \\ 0 & 0 \end{bmatrix};$$

$$C = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}$$

as well as:

$$\begin{aligned} a_1 &= -\left(\frac{1}{\tau_s \sigma} + \frac{(1-\sigma)}{\tau_r \sigma}\right); & a_2 &= \frac{M}{\sigma L_s L_r \tau_r}; & a_3 &= \frac{M}{\sigma L_s L_r}; \\ a_4 &= \frac{M}{\tau_r}; & a_5 &= \frac{1}{\tau_r}; & \tau_s &= \frac{L_s}{R_s}; & \tau_r &= \frac{L_r}{R_r}; \end{aligned}$$

The idea of the proposed stator currents estimator is based on the general theory of Luenberger observer [16], which allows the estimation of variable or unknown parameters of a system. The equation of the Luenberger observer is expressed in (5), where the symbol “ $\hat{\cdot}$ ” denotes the estimated values:

$$\begin{cases} \dot{\hat{X}} = A(\omega_r)\hat{X} + BU + K\xi \\ \hat{Y} = C\hat{X} \end{cases} \quad (5)$$

where:

$$\hat{X} = [\hat{i}_{s\alpha} \ \hat{i}_{s\beta} \ \hat{\psi}_{r\alpha} \ \hat{\psi}_{r\beta}]^T; \quad \hat{Y} = [\hat{i}_{s\alpha} \ \hat{i}_{s\beta}]^T;$$

$$\xi = [i_{s\alpha} - \hat{i}_{s\alpha} \ i_{s\beta} - \hat{i}_{s\beta}]^T$$

Since there is no information about the measured currents, the vector ξ becomes:

$$\xi = [-\hat{i}_{s\alpha} \ -\hat{i}_{s\beta}]^T$$

The gain matrix K is defined as follows:

$$K = \begin{bmatrix} K_1 & K_2 & K_3 & K_4 \\ -K_2 & K_1 & -K_4 & K_3 \end{bmatrix}^T$$

where:

$$K_1 = (k-1)\left(\frac{1}{\sigma \tau_s} + \frac{1}{\sigma \tau_r}\right)$$

$$K_2 = -(k-1)\omega_r$$

$$K_3 = (k^2 - 1) \left[\left(\frac{1}{\sigma\tau_s} + \frac{1}{\sigma\tau_r} \right) \frac{\sigma L_s M}{L_r} - \frac{M}{\tau_r} \right] + \frac{\sigma L_s M}{L_r} \left(\frac{1}{\sigma\tau_s} + \frac{1}{\sigma\tau_r} \right) (k-1)$$

$$K_4 = -(k-1) \frac{\sigma L_s M}{L_r} \omega_r$$

with k a positive gain.

The estimation is performed through the conservation of the state model (4) of the IM with the gain matrix K . This matrix ensures the convergence of the observer, and has been determined by the classical pole placement procedure. Then, replacing the adaptive mechanism by the measured rotational speed, as well as, feeding the observer with the stator voltages provided by the voltage synthesizer. This gives the stator currents estimation, as illustrated in Fig. 1.

Fig. 1. Proposed stator currents estimator.

B. Fault Detection, Isolation and System Reconfiguration

The logic-circuit presented in Fig. 2 is intended to ensure the fault detection, isolation, and system reconfiguration. The detection of failures is performed by analyzing the residual signal between the measured and estimated quantities, passing through a Low Pass Filter (LFP) to extract the useful signal that will be compared to a well-defined threshold ($Th=0.8$), then a proper estimation is used for the isolation and reconfiguration of the system.

Fig. 2. Fault detection, isolation and system reconfiguration scheme

As mentioned previously, two current sensors (in phase-a and phase-b) were used in the proposed method for measuring a and b line currents. The axis transformation presented in Fig. 3 developed by [17] and used in both [18], and [19], which is also used in the proposed FTC, in order to

have the component currents (α, β) using only the measurements of (a, b) components.

Fig. 3. Axis transformation model.

As shown in Fig. 3, the β -axis is aligned with the b -axis. Considering the equation of transformation from (a, b) to (α, β) , which is given in (6), it is clear that $i_{s\alpha}$ depends on the two-phase currents I_{sa} and I_{sb} , whereas the current $i_{s\beta}$ depends only on the current I_{sb} . Therefore, if the phase-a current sensor becomes faulty, only $i_{s\alpha}$ that will be affected. But, if the phase-b current sensor becomes faulty, both currents $i_{s\alpha}$ and $i_{s\beta}$ will be affected.

$$\begin{bmatrix} i_{s\alpha} \\ i_{s\beta} \end{bmatrix} = \begin{bmatrix} 2/\sqrt{3} & 1/\sqrt{3} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} I_{sa} \\ I_{sb} \end{bmatrix} \quad (6)$$

So, the faulty measured current components (α, β) must be replaced by the corresponding estimated currents. As a consequence, Table 1 shows the identification of the faulty sensors and the correct components of the estimated currents that will replace the erroneous components.

TABLE I. FAULTY SENSOR IDENTIFICATION AND CORRECT COMPONENT SELECTION

Sensor-a	Sensor-b	Za	Zb	OR	Proper selected components
Healthy	Healthy	0	0	0	$i_{sa\ mes}$ and $i_{sb\ mes}$
Faulty	Healthy	1	0	1	$i_{sa\ est}$ and $i_{sb\ mes}$
Healthy	Faulty	0	1	1	$i_{sa\ est}$ and $i_{sb\ est}$
Faulty	Faulty	1	1	1	$i_{sa\ est}$ and $i_{sb\ est}$

As presented in Fig. 2 and defined in Table I, it appears that in the case of *sensor-a* failure, fault detection part of the logic circuit generates an impulse $Z_a=1$, whereas, in the case of *sensor-b* failure, fault detection logic circuit generates an impulse $Z_b=1$. Once the faulty sensor is identified, it is isolated, and the system is reconfigured, using the fault isolation and system reconfiguration part of the logic circuit. The logic gate OR output is 1 when any one of its inputs Z_a or Z_b or both is 1 due to the effect of the failure of *sensor-b* on $i_{s\alpha}$ current. As a consequence, in the case of *sensor-b* failure, $i_{sa\ mes}$ is isolated and replaced by $i_{sa\ est}$.

IV. SIMULATION AND EXPERIMENTAL RESULTS

The proposed current sensor direct torque fault-tolerant control for induction motor drive is simulated in Matlab\Simulink environment using 4 kW induction motor parameters (see the Appendix). Fig. 4 presents the block diagram of the proposed method.

Figs. 8 and 9 give another test of the suggested FTC method with simulation and experimentation respectively, where a failure in *sensor-b* is performed, whereas *sensor-a* remains healthy. Simulation and experimental tests were started in healthy conditions until $t=1s$ for simulation test and $t=9.8s$ for experimental test, where *sensor-b* becomes faulty. Considering Figs. 8(a) and 9(a), it can be seen that $i_{s\alpha\ mes}$ is slightly affected by the failure of *sensor-b*, while $i_{s\beta\ mes}$ is significantly affected, which is explained previously in equation (6). The fault detection algorithm reacts quickly by generating an impulse $Z_b=1$, indicating that *sensor-b* is faulty, unlike Z_a which remains at 0.

meaning that *sensor-a* gives proper measurement. At this moment, *switch-b* switches to input 1 to replace $i_{s\beta\text{ mes}}$ by $i_{s\beta\text{ est}}$, and according to the output of the gate OR (see Table 1) *switch-a* switches to input 1 to replace $i_{s\alpha\text{ mes}}$ by $i_{s\alpha\text{ est}}$. Figs. 8(c) and 9(c) demonstrate sensor state indicators Z_a and Z_b . Figs. 8(d) and 9(d) for experimentation show the speed tracking performance of the IM drive before and after the failure occurrence.

Fig. 8. Simulation results when *sensor-b* is faulty and *sensor-a* remains healthy: (a) $i_{s\alpha}$ currents, (b) $i_{s\beta}$ currents, (c) fault indicator, and (d) reference and actual speeds.

Fig. 9. Experimental results when *sensor-b* is faulty and *sensor-a* remains healthy: (a) $i_{s\alpha}$ currents, (b) $i_{s\beta}$ currents, (c) fault indicator, and (d) reference and actual speeds.

C. Test of the proposed FTC when both *sensor-a* and *sensor-b* become faulty

Figs. 10 and 11 illustrate respectively the simulation and experimentation results obtained by applying the proposed FTC when the both sensors fail. The *sensor-a* failure is simulated at $t=1\text{s}$, while the *sensor-b* fault is simulated at $t=1.1\text{s}$ as shown in the Figs. 10(a) and 10(b). In the experimental test, *sensor-a* failure is appeared at $t=8.75\text{s}$, while *sensor-b* failure is appeared at $t=14.35\text{s}$ as can be seen in Figs. 11(a) and 11(b). While, Figs. 10(c) and 11(c) show the fault indicator signals (Z_a for *sensor-a* and Z_b for *sensor-b*). When the defect is suddenly introduced in the *sensor-a*, the fault detection mechanism has reacted quickly by generating a Z_a index equal to 1, indicating that *sensor-a* is faulty. Based on equation (6), the current $i_{s\beta\text{ mes}}$ will not be affected, which is visible in Figs. 10(b) and 11(b), where the current $i_{s\beta\text{ mes}}$ remains healthy from 0 to 1.1s in simulation and until 14.34s in experimentation. According to Table 1, the selected currents to isolate the faulty measurement are: $i_{s\alpha\text{ est}}$ and $i_{s\beta\text{ mes}}$. After 1.1s in

simulation and 14.35s in experimentation, a fault has been introduced in *sensor-b*, at this moment, the fault indicator Z_b becomes 1, confirming *sensor-b* failure. Referring to equation (6), we can see that the currents $i_{s\alpha}$ and $i_{s\beta}$ both depend on the state of the measurement of *sensor-b*, which is confirmed in Figs. 10(a) and 11(a) where the degree of severity of the fault in the current $i_{s\alpha\text{ mes}}$ is increased. Therefore, the isolation and reconfiguration algorithm chooses $i_{s\alpha\text{ est}}$ and $i_{s\beta\text{ est}}$ (see Table 1). Figs. 10(d), 11(d) and 10(e), 11(e) clearly show that speed and torque maintain their performance and remain uninterrupted, even under the worst possible conditions, when the both current sensors fail. In addition, Figs. 10(f) and 11(f) show the constant estimate of stator flux.

Fig. 10. Simulation results when both *sensor-a* and *sensor-b* become faulty: (a) $i_{s\alpha}$ currents, (b) $i_{s\beta}$ currents, (c) fault indicator, (d) reference and actual speeds, (e) load and electromagnetic torque, and (f) stator flux trajectory.

Fig. 11. Experimental results when both *sensor-a* and *sensor-b* become faulty: (a) $i_{s\alpha}$ currents, (b) $i_{s\beta}$ currents, (c) fault indicator, (d) reference and actual speeds, (e) load and electromagnetic torque, and (f) stator flux trajectory.

V. CONCLUSION

This paper presents a direct torque fault-tolerant control diagram for current sensors failures in the induction motor drives. For the identification of a sensor failure, a logic circuit is used in the phases where the current sensors are located, which is able to detect the failures of the used current sensors. A current estimator is used to estimate the stator currents. Immediately after the failure of the current sensor, a decision logic circuit automatically selects the correct current signal to maintain the operation of the system. Simulation and experimental results show the effectiveness of the proposed method, where the fault detection is accomplished with fast dynamics, and the drive is performing successfully, without compromising the control system.
